7 **The Concept of Species and Its**
 8 **definition: An Historical Perspective**

9 Species are the fundamental units of biological
 10 classifications. Understanding the concept of spe-
 11 cies is important both because species are the units
 12 of comparison across different biological disci-
 13 plines including behavior, evolution, genetics,
 14 ecology, anatomy, development, and molecular
 15 biology, and because it plays an important role
 16 for the formulation of environmental law and eco-
 17 logical conservation. Species are also the currency
 18 by which biologists measure biodiversity. How-
 19 ever, biologists largely disagree on the definition
 20 of “species.”

21 Attempts to define the concept of species date
 22 back to the Greek philosophers Plato and Aris-
 23 totle, who viewed the world as we know it as a
 24 flawed shadow of the eternal and immutable
 25 world of ideas. Indeed, the word “species” origi-
 26 nates from the Latin “kinds” which is a translation
 27 of the Greek word *eidōs* (idea). According to this
 28 view, the world we live in is imperfect and vari-
 29 able and it is only a projection of the ideas that are
 30 real and unchanging.

However, it was an English naturalist, John 31
 Ray (1628–1705) who introduced for the first 32
 time the concept of “species” in biology. In his 33
 1686 *Historia Plantarum* he wrote: 34

In order that an inventory of plants may be begun 35
 and a classification of them correctly established, 36
 we must try to discover criteria of some sort for 37
 distinguishing what are called ‘species’. After a 38
 long and considerable investigation, no surer crite- 39
 rion for determining species has occurred to me 40
 than distinguishing features that perpetuate them- 41
 selves in propagation from seed. (quoted in Briggs 42
 and Walters 2016, p. 4) 43

In other words, according to Ray, species are 44
 those groups of organisms that resemble their 45
 parents. Although Ray acknowledged that there 46
 can be some variants or “accidents” – as he called 47
 them – within a species, such as different heights, 48
 scents, or colors, organisms that differ by these 49
 characteristics should not be considered as differ- 50
 ent species. Ray, also, tried to reconcile the idea of 51
 “species” with the Bible account of Creation, and 52
 believed that all species were created at the same 53
 time and no new species could come into exist- 54
 ence. While Ray is regarded as the first person 55
 who introduced the concept of species in biolog- 56
 ical terms, Carl Linnaeus (Carl von Linné, 57
 1707–1778) is considered the true father of mod- 58
 ern biological taxonomy and classification. In his 59
Systema Naturae (first edition 1735), Linnaeus for- 60
 mulated a system to classify organisms, by iden- 61
 tifying five categories: kingdom, class, order, 62
 genus, and species. Before Linnaeus, the 63

64 classification of organisms was somewhat arbitrary, and organisms were often given long
65 names that could be easily altered, making it
66 more difficult for different biologists to understand
67 what species they were referring to. Linnaeus was the first one to formulate the
68 classification based on organism similarities, and
69 to designate the binomial system (*genus* + *species*) to classify organisms. Interestingly, in the
70 first editions, Linnaeus still considered species as fixed, a view that emerges also in other publica-
71 tions. In *Critica Botanica* (1737), for example, he
72 defended the concept of fixity of species:

77 All species reckon the origin of their stock in the
78 first instance from the veritable hand of the
79 Almighty Creator: for the Author of Nature, when
80 He created species, imposed on his Creations an
81 eternal law of reproduction and multiplication
82 within the limits of their proper kinds. He did
83 indeed in many instances allow them the power of
84 sporting in their outward appearance, but never that
85 of passing from one species to another. (quoted in
86 Briggs and Walters 2016, p. 6)

87 Over the years, however, Linnaeus's observa-
88 tions led him to realize that species are not immu-
89 table entities as different species of organisms
90 cannot always be easy to distinguish, and in his
91 tenth edition of *Systema Naturae*, he acknowledged
92 that new species of organisms can be formed
93 through intergeneric crosses. He even wrote a
94 document, *Plantae Hybridae* (1751), where he
95 listed 100 plants that might have been considered
96 as hybrids.

97 One of the most influential figures in human
98 history, because of his theory of evolution by
99 natural selection, is undoubtedly Charles Darwin
100 (1809–1882), author of the *On the Origin of the*
101 *Species* (first edition: 1859). There is still large
102 debate on Darwin's concept of species, mainly
103 because of largely contradicting statements that
104 emerged from his book. In some cases, Darwin
105 (1859) appears to consider the concept of "spe-
106 cies" as a human construct: in p. 52 he wrote:

107 I look at the term species, as one arbitrarily given for
108 the sake of convenience to a set of individuals
109 closely resembling each other, and that it does not
110 essentially differ from the term variety, which is
111 given to less distinct and more fluctuating forms.

112 While in a letter dated 1860, he wrote:

How absurd that logical quibble—'if species do not
exist how can they vary?' As if any one doubted
their temporary existence?

116 The current view that tries to reconcile these
117 apparently contradicting opinions Darwin held on
118 the concept of species is that Darwin did believe
119 that the specific species taxa exist, but he
120 questioned the existence of the "species" category,
121 given that, according to Darwin, there cannot be a
122 clear boundary between species and variety. In other
123 words, the variation that distinguishes each set of
124 individuals is so continuous that setting the bounda-
125 ries to attribute to these different populations the
126 rank of species appears to be more a convention than
127 a reality. This view sets Darwin's approach apart
128 from earlier naturalists' idea that each species was
129 produced in the current form by a Creator, with only
130 little variation between individuals belonging to the
131 same species.
132

Current Concepts of Species

133 A high number of species concepts has been
134 developed over the years: Wilkins (2006) identi-
135 fied a total of 26 definitions of species, while
136 Zachos (2016), more recently, counted 32 species
137 concepts. According to Wilkins (2006), only
138 seven of these concepts are really independent:
139 *morphological*, *biological*, *evolutionary*, *genetic*,
140 *taxonomic*, *ecological*, and *agamospecies con-*
141 *cepts* and, as Wilkins himself pointed out, some
142 of these concepts are not definitions of what spe-
143 cies are, but how biologists can identify them. In
144 other words, most of these concepts do not ques-
145 tion whether species are concrete describable
146 objects in nature, but how best to define this
147 class of objects so that any other object that pos-
148 sesses attributes that do not belong to this class of
149 object can be excluded. Here some main species
150 concepts, namely the morphological, biological,
151 evolutionary, genetic, ecological, and
152 agamospecies, will be discussed, while a complete
153 and recent list of all the concepts can be
154 found in Zachos (2016).
155

156 Morphological Species Concept

157 Under the Morphological Species Concept,
 158 Cronquist (1978) defined the species as “the
 159 smallest groups that are consistently and persist-
 160 ently distinct, and distinguishable by ordinary
 161 means” (quoted in Wilkins 2009, p. 214).
 162 According to this concept, the species can be
 163 distinguished on the basis of their morphological
 164 features. This approach is also called *essentialist*,
 165 as, under this view, members of a species can be
 166 identified by their essential characteristics, or
 167 *typological* since it posits that all the diversities
 168 on earth reflect a limited number of “types.” While
 169 this concept dates back to Aristotle and Plato’s
 170 concept of “ideas” and was adopted by Linnaeus
 171 and other earlier naturalists to classify the organ-
 172 isms, this view has been largely abandoned on the
 173 ground that individuals belonging to the same
 174 species can display large intraspecific differences,
 175 because of marked sexual dimorphism, aging, or
 176 polymorphism or perfectly distinct species can be
 177 morphologically similar to each other (the-so
 178 called cryptic species).

179 The Biological Species Concept

180 The Biological Species Concept is probably one
 181 of the most cited definitions of species. It was first
 182 defined by Dobzhansky (1935) as follows:

183 A species is a group of individuals fully fertile inter-
 184 se, but barred from interbreeding with other similar
 185 groups by its physiological properties (producing
 186 either incompatibility of parents or sterility of the
 187 hybrids, or both)

188 This definition was then expanded by Mayr
 189 (1940) who originally defined species as

190 A group of populations which replace each other
 191 geographically or ecologically and of which the
 192 neighboring ones inter-grade or interbreed wher-
 193 ever they are in contact or which are potentially
 194 capable of doing so (with one of more of the
 195 populations) in those cases where contact is pre-
 196 vented by geographical or ecological barriers.

197 In other words, species are groups of individ-
 198 uals who interbreed but who are reproductively
 199 isolated from other groups. Mayr (1969) defined a
 200 species as both a *reproductive unit*, in which
 201 members seek each other to reproduce, an *ecolog-*
 202 *ical unit*, as individuals of a species share the same

environment, and a *genetic unit*, whose members 203
 share the same set of genetic information. There 204
 are two main mechanisms by which reproductive 205
 isolation can be achieved: *pre-zygotic* and *post-* 206
zygotic. Pre-zygotic isolation includes: 207

- *Ecological isolation*: when different 208
 populations occupy different geographical 209
 areas or different ecological niches. 210
- *Behavioral isolation*: when different 211
 populations display different behaviors that 212
 prevent them from interbreeding, such as dif- 213
 ferent courtship rituals, mating calls, or chem- 214
 ical signals. 215
- *Temporal isolation*: when different 216
 populations produce gametes at different 217
 times. This is particularly common in plants 218
 that exhibit different flowering periods. 219
- *Mechanical isolation*: when females and males 220
 have reproductive organs that are compatible 221
 only among members of their own species. 222
 This type of reproductive isolation is particu- 223
 larly common in insects. 224

Post-zygotic isolation includes: 225

- *Hybrid viability*: when the hybrid dies 226
 prematurely 227
- *Hybrid infertility*: when the offspring that is 228
 produced by the two different species is 229
 infertile 230

There are a number of problems with the Bio- 231
 logical Species Concept: 232

1. Mayr’s biological concept definition can only 233
 apply to sexual organisms but it does not work 234
 for those organisms who do not reproduce 235
 sexually, such as protozoans. 236
2. The biological species concept can only be 237
 applied to the species that share the same 238
 space at the same time, making the definition 239
 inapplicable to species that live at different 240
 times (i.e., fossils) or in different geographic 241
 regions. This is because it is hard to test 242
 whether two populations that live at different 243
 times or in different areas can reproduce. In 244

p. 121 Mayr (1940) states that: “the application of a biological species definition is possible only in well-studied taxonomic groups, since it is based on a rather exact knowledge of geographical distribution and on the certainty of the absence of interbreeding with other similar species.” To address this issue, Mayr (1970) took out the word “potentially” by the Biological Species Concept and defined species “as those groups of interbreeding natural populations that are reproductively isolated from other groups” (p. 12).

3. Finally, there is a plethora of cases in which interbreeding between different species results in fertile offspring. Some *genera* are renowned for including species that have a high ability to interbreed, such as the genera *Cervus*, *Lepus*, *Canis*, and *Macaca*. Hybridization appears to be particularly common in birds: Grant and Grant (1992) calculated that about 1 in 10 species of birds are known to have bred in nature with another species. Mayr (1970) tried to solve the problem of hybridization by revising his definition of “isolating mechanism” to “biological properties of individuals which prevent the interbreeding [fusion] of populations” (p. 56). In other words, these isolating mechanisms would not be able to guarantee the complete lack of interbreeding between different species, but it would prevent the complete fusion between them.

276 The Evolutionary Species Concept

277 The Evolutionary Species Concept tried to solve
278 the nondimensional nature of the Biological Species
279 concept by defining species as “a lineage
280 (an ancestral-descendant sequence of
281 populations) evolving separately from others and
282 with its own evolutionary role and tendencies”
283 (Simpson 1961, p. 153). The second part of the
284 definition (“own evolutionary role and tendencies”)
285 is particularly important as it implies that
286 there should be some sort of biological relevance
287 when assigning a group of individuals the status
288 of species, and it precludes considering species
289 from any ephemeral offshoot of the species, such
290 as small captive populations. The main criticism is
291 that this concept is not an operational definition as

it does not help to identify whether a specific class
292 of individuals belongs to a specific species. Fur-
293 thermore, from the definition of Evolutionary
294 Species Concept, it is unclear which level of lin-
295 eages we should consider the species level, as
296 lineages exist at different levels. Wiley and May-
297 den (2000) solved this issue by identifying evolu-
298 tionary species as those tokogenetic entities
299 “composed by parts (individual organisms) linked
300 by reproduction and manifested by tokogeny”
301 (p. 74) where tokogeny is defined as the biological
302 relationship between parents and offspring or,
303 more generally, between ancestors and
304 descendants. 305

The Genetic Species Concept 306

Baker and Bradley (2006) defined a genetic spe-
307 cies as a “group of genetically compatible inter-
308 breeding natural populations that is genetically
309 isolated from other such groups.” While the core
310 aspect of the Biological Species Concept is repro-
311 ductive isolation, the key element at the basis of
312 the Genetic Species Concept is *genetic* isolation,
313 produced by an accumulation of genetic changes. 314
The initial criticisms against this concept is that it
315 would be hard to accurately estimate genetic dis-
316 tance, especially considering our lack of knowl-
317 edge of an organism’s genetic information. 318
However, recent genetic advances have made it
319 possible to assess genetic differences between
320 organisms. For example, an examination of the
321 variation in mitochondrial cytochrome-*b* gene
322 sequence across several mammalian species sug-
323 gests that genetic distance values lower than 2%
324 indicate intraspecific variation (hence the organ-
325 isms belong to the same species), values >11%
326 represent different species, while values that range
327 between 2% and 11% deserve further investiga-
328 tion in order to understand whether they should be
329 considered the same or different species (Bradley
330 and Baker 2001). The important difference
331 between the Genetic and Biological Species Con-
332 cepts is that while the former considers
333 populations as distinct species even if there is
334 gene flow and their hybridization produces fertile
335 offspring, the Biological Species Concept would
336 recognize these two populations as the same spe-
337 cies (and different subspecies). There are 338

339 numerous examples in nature of populations that
 340 might appear to belong to the same species, but
 341 genetic analyses reveal as different species, and
 342 Baker and Bradley (2006) estimate that there are
 343 more than 2000 unrecognized species.

344 The Ecological Species Concept

345 The Ecological Species Concept was introduced
 346 by Van Valen (1976), under the idea that differ-
 347 ences in ecological niches, more than genes, are
 348 the primary drivers of evolution and that repro-
 349 ductive isolation plays a minor role in the forma-
 350 tion of the species.

351 Van Valen (1976) defined species as “a lineage
 352 (or a closely related set of lineages) which
 353 occupies an adaptive zone minimally different
 354 from that of any other lineage in its range and
 355 which evolves separately from all lineages outside
 356 its range.” According to Van Valen (1976), an
 357 adaptive zone is considered the part of the envi-
 358 ronment that contains a specific set of resources
 359 along with certain levels of predation and parasit-
 360 ism, and can have boundaries that are either pre-
 361 existing or defined by the species that are living
 362 there. Under this concept, populations that live in
 363 separate areas can still be considered as belonging
 364 to the same species if they are under the same
 365 ecological pressures. Grant (1992) pointed out
 366 that the idea that ecological adaptations play an
 367 important role for the formation of species is not
 368 new and even the “fathers” of the Biological Spe-
 369 cies Concept acknowledged the importance of
 370 ecological factors. In the *Genetics and Origin of*
 371 ~~the~~ *Species* Dobzhansky (1951), for instance,
 372 highlighted how the phenotypic and genetic dis-
 373 continuities between species are probably related
 374 to differences in their ecological niches, and that
 375 reproductive isolation manages to fix these phe-
 376 notypic and genetic differences. The main criti-
 377 cism of the Ecological Species Concept, however,
 378 is that we cannot have a priori knowledge of what
 379 makes an ecological niche and, in fact, researchers
 380 often use ecological differences between species
 381 to characterize their ecological niches (Grant
 382 1992). Furthermore, in many species, different
 383 morphs or different sexes can occupy different
 384 niches and so we cannot reliably use ecological
 385 differentiation as a diagnostic of a species.

The Agamospecies Concept

386 Many of the abovementioned concepts do not
 387 apply to organisms who do not reproduce sexually
 388 and who lack genetic exchange. This is because
 389 the key aspects of the Biological and Genetic
 390 Species Concepts are reproductive and genetic
 391 isolation, respectively, and Wiley and Mayden
 392 (2000) had to drop the word “population” from
 393 their definition of Evolutionary Species Concept
 394 in order to be able to include asexual organisms.
 395 The first definition of agamospecies concept was
 396 given by Turesson (1929), who defined species as
 397 “an apomict-population the constituents of which,
 398 for morphological, cytological or other reasons,
 399 are to be considered as having a common origin”
 400 (quoted in Zachos 2016, p. 98). This definition
 401 can be considered as a “Morphological Species
 402 Concept” applied to asexual organisms. Another
 403 definition was provided by Cain (1954) who
 404 defined agamospecies as “those forms to which
 405 [the biological species concept] cannot apply
 406 because they have no true sexual reproduction.”
 407 The problem with this definition is that it defines
 408 the “species” as *not being* something else. A better
 409 definition, which was originally used to define
 410 viruses, was given by Eigen (1993), who coined
 411 the term *quasispecies*, defined as “a self-
 412 sustaining population of sequences that reproduce
 413 themselves imperfectly but well enough to retain a
 414 collective identity over time.” The concept of
 415 quasispecies hinges on the observation that in a
 416 cluster of genotypes of viruses there is an optimal
 417 (or wild) type with specific mutations that make it
 418 particularly adapted to a specific environment,
 419 from which other viruses reproduce. This defini-
 420 tion is very similar to the *Ecological Species Con-*
 421 *cept* and can be applied more generally to asexual
 422 organisms, which is why Wilkins (2009) con-
 423 siders *agamospecies* and *quasispecies* synonyms.
 424

Modes of Speciation

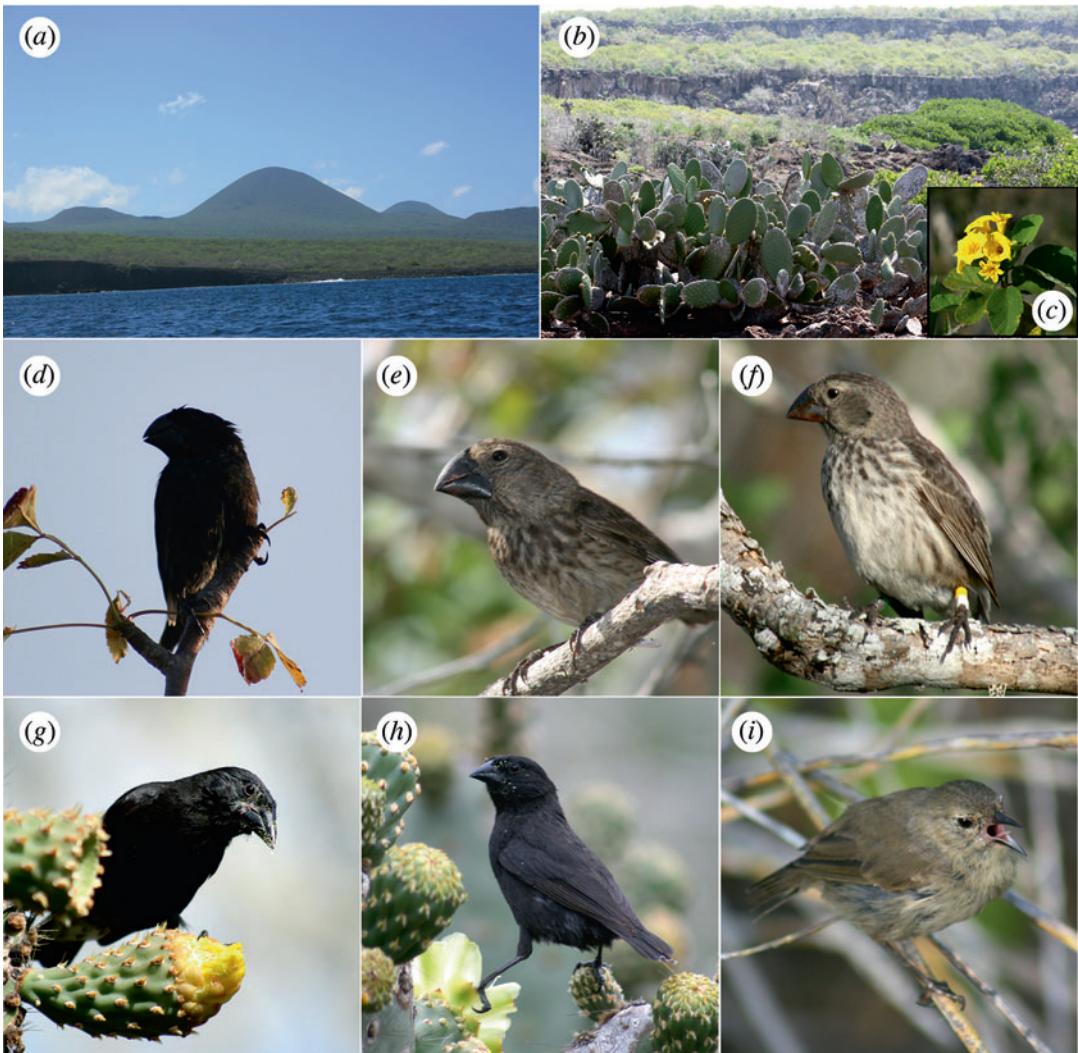

425 Speciation (or *cladogenesis*) is the biological pro-
 426 cess by which species originates from the ulti-
 427 mately irreversible splitting of one population
 428 lineage in two or more lineages. Importantly, this
 429 evolutionary process is different from the
 430

431 *anagenesis* that occurs when a population lineage
432 gradually changes over time until it reaches the
433 point when it becomes sufficiently distinct from
434 its ancestor. There are three main modes of speci-
435 ation: *allopatric*, *sympatric*, and *parapatric*.

- 436 • *Allopatric (or geographic) speciation* is the
437 most common form of speciation and occurs
438 when different populations from the same spe-
439 cies become isolated and no genetic exchange
440 occurs between them. These isolated
441 populations undergo genetic changes over
442 time due to mutations, migration, or other evo-
443 lutionary forces, to the extent that they become
444 reproductively isolated from each other. There
445 are two main forms of allopatric speciation:
446 *dichopatric* and *peripatric*. Dichopatric speci-
447 ation arises when populations inhabiting a spe-
448 cific geographic area become isolated due to
449 the development of a new geographic barrier
450 that splits the original population into two or
451 more groups. Peripatric speciation occurs
452 when a single gravid female or few individuals
453 of a species colonize a new geographic area.
454 This, in turn, results in *genetic drift* and *bottle-*
455 *neck effects* that lead to genetic changes and
456 reproductive isolation from the original spe-
457 cies. Classic examples of allopatric speciation
458 are Darwin's Galapagos finches: these are
459 15 species of birds inhabiting different islands
460 on the Galapagos archipelagos, located in the
461 Pacific Ocean off South America. Over mil-
462 lions of years, these bird species have evolved
463 different types of beaks of different size and
464 shape that are particularly adapted to the type
465 of food they eat (Abzhanov 2010). For exam-
466 ple, ground finches, like *Geospiza*
467 *magnirostris*, *G. fortis*, and *G. fuliginosa*,
468 have stout beaks for eating seeds, while cactus
469 finches, such as *G. conirostris*, have longer
470 more pointed beaks to feed on nectar or getting
471 seeds from cacti (Fig. 1).
- 472 • *Sympatric speciation* occurs when a new spe-
473 cies originates in the same geographic area of
474 the parental population. It is less common than
475 allopatric speciation and can occur, for
476 instance, when part of the population starts
477 using a new niche, and is more likely to occur

478 in herbivorous insects that display a particu- 478
479 larly specialized relationship with their host 479
480 plants. A textbook example of sympatric spe- 480
481 ciation is the apple maggot *Rhagoletis* 481
482 *pomonella*: apple maggots used to lay their 482
483 eggs exclusively in hawthorns, which are 483
484 native to America. However, 200 years ago, 484
485 they started using also domestic apples, which 485
486 were introduced to America by immigrants. 486
487 Since males generally look for mates on the 487
488 type of fruit they grew up in and females lay 488
489 their eggs on the type of fruit they grew up in, 489
490 hawthorn flies generally mate with hawthorn 490
491 flies and apple flies mate with apple flies pre- 491
492 venting gene flow between the two types of 492
493 flies and providing the first step for sympatric 493
494 speciation. 494

- 495 • *Parapatric speciation* occurs when individuals 495
496 from a continuous population tend to mate with 496
497 geographic neighbors more often than with 497
498 individuals belonging to other areas of the 498
499 population's range due to differences in the 499
500 same environment. These local populations 500
501 are called *demes*. Different demes of a popula- 501
502 tion are not isolated from each other, as indi- 502
503 viduals can move from a deme to the other but 503
504 given that individuals tend to mate only with 504
505 members of their own demes, they might be 505
506 subject to specific selective pressures that can 506
507 lead them to become a whole new species. 507
508 A species who might be undergoing parapatric 508
509 speciation is *Anthoxanthum odoratum*. This 509
510 plant species grows in mining zones, whose 510
511 soil is contaminated with high levels of heavy 511
512 metals, and members of this species have 512
513 developed a high tolerance for heavy metal. 513
514 Although these tolerant individuals live close 514
515 to the same species of plants that do not grow 515
516 in contaminated ground, tolerant and non- 516
517 tolerant plants have evolved during different 517
518 flowering times. This temporal isolation indi- 518
519 cates that tolerant individuals would breed only 519
520 with tolerant individuals and nontolerant indi- 520
521 viduals would reproduce only with nontolerant 521
522 individuals, providing the first step for 522
523 (parapatric) speciation. 523

Species, Fig. 1 (a) Galápagos Islands, such as Isla Floreana, are volcanic islands visited by Charles Darwin in 1835; (b) bushes of the prickly pear cactuses (*Opuntia helleri*) on Isla Genovesa (Tower Island); (c) flowers of the yellow geiger (*Cordia lutea*); (d) male of the large ground finch (*Geospiza magnirostris*) singing during the rainy season; (e) female of the large ground finch

(*G. magnirostris*) on Isla Genovesa; (f) female of the medium ground finch (*G. fortis*) on Isla Santa Cruz; (g) male large cactus finch (*G. conirostris*); (h) male sharp-beaked finch (*G. difficilis*) feeding on cactus flowers on Isla Genovesa; (i) male warbler finch (*Certhidea fusca*) singing next to its nest (Abzhanov 2010; © 2010 The Royal Society)

525 **Discovery of New Species**

526 It is generally estimated that 15,000–18,000 new
 527 species are discovered every year, of which half
 528 are insects. This list includes also correction in the
 529 taxonomy or species that are moved from a family
 530 to another. Since 2008, the SUNY College of
 531 Environmental Science and Forestry releases on

May 23rd (which corresponds to Carl Linnaeus' 532
 birthday) the list of the top 10 new species dis- 533
 covered the previous year ([http://www.esf.edu/ 534](http://www.esf.edu/top10/)
[top10/](http://www.esf.edu/top10/)).

There are different ways in which a new spe- 536
 cies can be discovered: 537

538 – *Expedition in remote areas.* There are many
 539 areas on earth that have not been explored
 540 yet, and can be home to species that have
 541 never been described. In December 2005, for
 542 instance, an international team of 11 scientists
 543 from Australia, the United States, and Indone-
 544 sia travelled to the, until then, unexplored areas
 545 of Foja Mountains and discovered numerous
 546 new species ([http://news.bbc.co.uk/2/hi/sci-
 547 ence/nature/4688000.stm](http://news.bbc.co.uk/2/hi/science/nature/4688000.stm)). These included:
 548 40 new species of mammals, many new plant
 549 species, including five new species of palms,
 550 four new species of butterflies, twenty new
 551 species of frogs, and numerous new bird spe-
 552 cies. In some cases, researchers identify new
 553 species on the basis of the vocalizations they
 554 produce. Recently, Svensson et al. (2017)
 555 described a new species of dwarf bush-baby
 556 inhabiting Angola's Kumbira Forest which
 557 produces a different type of call from the
 558 other 18 known bush-baby species.

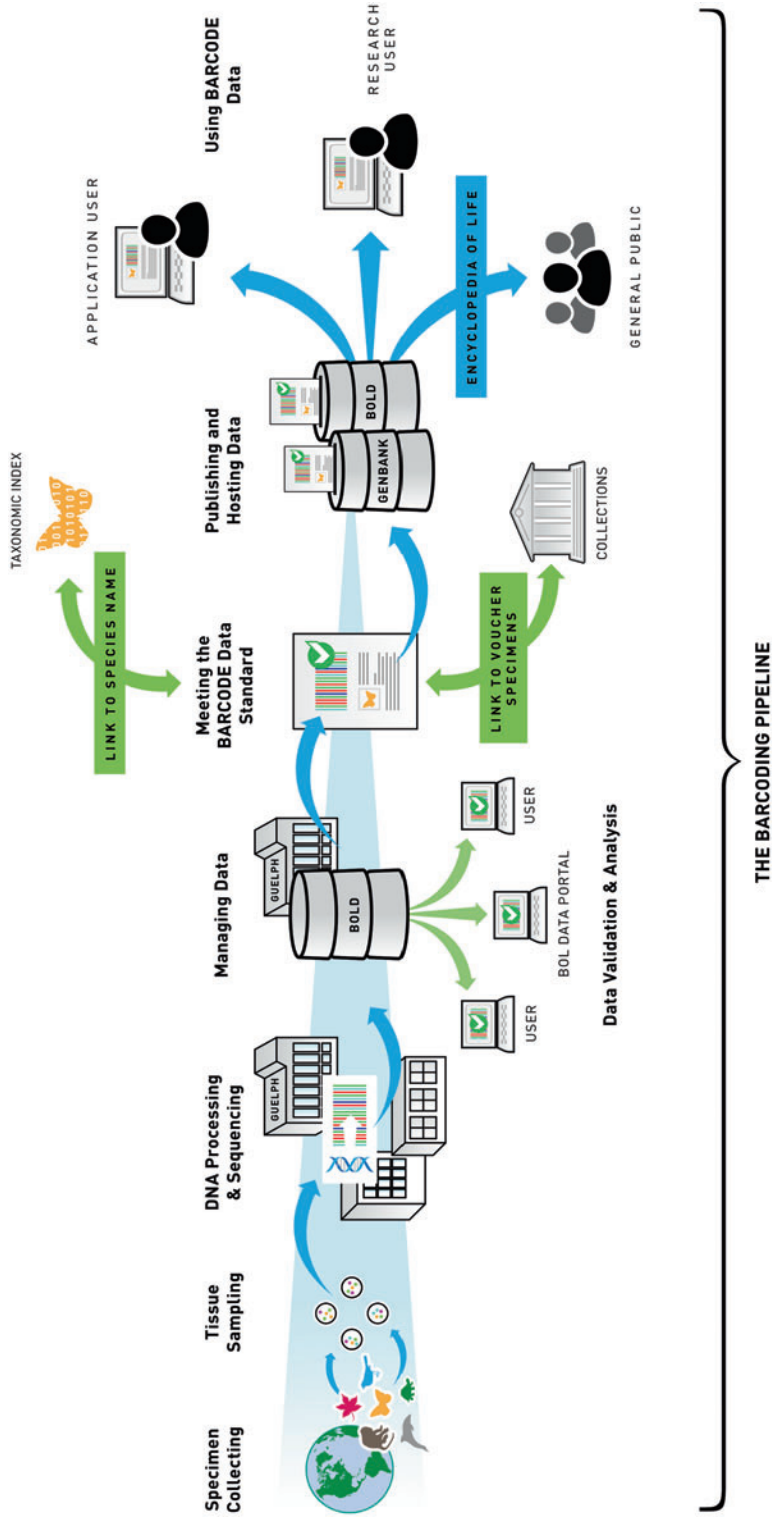

559 – *Examination of museum specimens.* New spe-
 560 cies can also be discovered in museum collec-
 561 tions, where they were collected 50 or
 562 100 years ago but their taxonomic classifica-
 563 tion was overlooked or specimens were often
 564 mislabeled. Recently, for example, Helgen
 565 et al. (2013) have described a new species of
 566 carnivorous mammal, the olinguito
 567 (*Bassaricyon neblina*), that lives in the forests
 568 of Andes, Ecuador, and Colombia. Helgen and
 569 colleagues analyzed the fur and bones of the
 570 specimens that were stored in several museum
 571 collections and, through DNA testing, found
 572 out that this was a new species. Several zoos in
 573 the USA probably exhibited an olinguito
 574 between 1967 and 1976, but keepers mistook
 575 it for its close relative, olinga, and could not
 576 understand why the olinguito could not breed.
 577 The olinguito eventually died without being
 578 properly identified.

579 – *Genetic analyses.* The advancement of DNA
 580 techniques has offered researchers the oppor-
 581 tunity to identify new species even when they
 582 are morphologically similar to another species
 583 and live in the same area. These species are
 584 also called cryptic species. DNA barcoding has
 585 become the most common technique to detect

new species (Hebert et al. 2003). Through this
 586 technique, DNA is extracted from specimens
 587 that can be collected from the field, from
 588 museums, zoos, or other sources. A region of
 589 this DNA is then isolated. This region is com-
 590 monly a 648 base-pair region in the mitochon-
 591 drial cytochrome c oxidase I gene ("COI"),
 592 located in the mitochondrial DNA, which has a
 593 mutation rate that is slow enough to be identi-
 594 cal within the same species but fast enough to
 595 be different between species. The use of this
 596 DNA region to identify new species has been
 597 shown to be effective for many animal groups,
 598 such as birds, fish, butterflies, but not for
 599 plants, for which two DNA regions in the chlo-
 600 roplast are used instead. Once this region is
 601 isolated, its copies are replicated and
 602 sequenced. The sequence is then compared to
 603 the sequences of known species contained in
 604 the Barcode of Life Data Systems (BOLD) to
 605 understand whether the species is already
 606 known or is a new species (Fig. 2). Recently,
 607 barcode analysis has been used to identify a new
 608 gibbon species *Hoolock tianxing* (common
 609 name: skywalker hoolock gibbon), which is
 610 distributed on the east of Irrawaddy-Nmai
 611 Hka Rivers in China and had been previously
 612 considered to be the same species as
 613 *H. leuconedys* (Fan et al. 2017). Although
 614 researchers had suspected that the two species
 615 were different, due to differences in morphol-
 616 ogy and vocalization patterns, only genetic
 617 analyses confirmed that the two were actually
 618 distinct species.
 619

620 Conclusion: The Importance of 621 Taxonomy for Conservation 622

623 Taxonomy provides an important tool for the con-
 624 servation of the species. The International Union
 625 for the Conservation of Nature (IUCN) is an orga-
 626 nization that monitors the conservation status of
 627 the organisms, and in its Red List of Threatened
 628 Species, it classifies the species extinction risk
 629 into (1) Least Concern, (2) Near-Threatened,

Species, Fig. 2 Basic workflow for generating DNA barcodes (Image courtesy: Kris Jett; © International Barcode of Life)

630 (3) Threatened (divided into Vulnerable, Endan-
 631 gered, and Critically Endangered), and (4) Extinct.
 632 By March 2014, among the 71,576 terrestrial and
 633 freshwater species assessed, 860 were classified
 634 as extinct or extinct in the wild, 21,286 were
 635 categorized as threatened, and 4286 were deemed
 636 critically endangered. Of the 6041 marine species
 637 for which we have enough data to assess their
 638 extinction risk, 16% were classified as threatened
 639 and 9% as near-threatened. Although the extinc-
 640 tion of a species is a natural phenomenon that
 641 occurs at a rate of one to five species per year,
 642 the most recent estimates suggest that the current
 643 rate of extinction is 1000–10000 times higher and
 644 is largely human-driven (Pimm et al. 2014). Out
 645 of an estimated 8.7 (\pm 1.3) million of eukaryotic
 646 species, only about 1.2 million species have been
 647 catalogued, leaving a total of 86% species on
 648 Earth and 91% of species in the ocean still
 649 undiscovered (Mora et al. 2011). With the high
 650 extinction rate that species face, many species
 651 disappear before they are discovered. In this con-
 652 text, identifying new species is key for their pro-
 653 tection before they become extinct. Assigning the
 654 rank of “species” to a population is, thus, impor-
 655 tant both because it gives them legal protection
 656 and because it increases the awareness that the
 657 population is indeed unique (Zachos 2016).
